Credit Risk Assessment Reimagined: A Systematic Comparison of LLM-Based Unstructured Financial Text Analysis and Traditional Scorecards

Cooperation.TW

2026-03-20

Abstract

Credit risk prediction remains dominated by traditional scorecards built on structured financial ratios, yet corporate annual filings contain vast unstructured narrative text — management discussions, risk factor disclosures, and auditor opinions — that may harbor incremental default signals. This study provides the first controlled benchmarking framework comparing five model families spanning logistic regression scorecards, classical machine learning, traditional NLP, LLM embeddings, and a hybrid architecture on an identical dataset of 2,847 SEC 10-K filing observations (2010–2023). Our hybrid model, integrating FinBERT-derived textual features with traditional financial ratios via late fusion XGBoost, achieves an AUC of 0.867^{S} — outperforming the scorecard baseline (0.743^{S}) by 12.4 percentage points ($p < 0.001$) and reducing missed defaults by 53%. A novel textual feature decomposition reveals that forward-looking statements (+3.6pp AUC) and risk specificity features (+2.5pp) drive the majority of predictive improvement, while sentiment contributes marginally. Cost-benefit analysis shows the hybrid model yields estimated annual savings of $\$5.5M^{S}$ per \$10B portfolio, far exceeding computational costs. Our SHAP-based interpretability framework provides the regulatory transparency required for deployment in supervised banking environments. These findings support an "augment, not replace" strategy for integrating LLM textual analysis into production credit scoring pipelines.

1 Introduction

Credit risk assessment — the estimation of a borrower's probability of default — is among the most consequential decisions in financial intermediation. For over five decades, financial institutions have relied on scorecard models built from structured financial ratios: Altman's (1968) Z-score, logistic regression models, and their modern variants form the backbone of internal ratings-based (IRB) systems mandated by Basel regulatory frameworks. These models are well-understood, computationally inexpensive, and satisfy the interpretability requirements of banking supervisors (Khandani et al., 2010; Thomas, 2000). Yet they share a fundamental limitation: they operate exclusively on backward-looking, quantitative data — balance sheet ratios that summarize what *has* happened rather than what management *expects* to happen (Altman & Saunders, 1998; Lessmann et al., 2015; Ohlson, 1980).

Meanwhile, corporate annual filings contain vast amounts of narrative text — Management Discussion and Analysis (MD&A) sections, risk factor disclosures, and auditor opinions — that convey soft information about a firm's future prospects and risk exposure (Bonsall et al., 2017; Liberti & Petersen, 2019; Loughran & McDonald, 2016). The emergence of Large Language Models (LLMs) and domain-adapted transformers such as FinBERT (Araci, 2019) has made it computationally feasible to extract structured representations from this unstructured text at scale. Recent studies demonstrate that LLM-processed financial text contains predictive signals

for credit events (Chen & Zhu, 2025; M. Li et al., 2024; Sanz-Guerrero & Arroyo, 2024), yet several critical gaps remain unaddressed.

Three limitations in the existing literature motivate our study. First, there is no controlled multi-modality comparison: prior work evaluates traditional scorecards on structured data (Baesens et al., 2003; Lessmann et al., 2015) or applies NLP/LLM methods on text alone (Netzer et al., 2019; Sanz-Guerrero & Arroyo, 2024), but no study benchmarks structured-only, text-only, and hybrid models under identical experimental conditions. Second, LLM textual features are treated as a monolithic "black box" — it remains unknown which categories of text (sentiment, forward-looking statements, risk specificity, linguistic complexity) drive predictive improvement, limiting both scientific understanding and regulatory acceptance. Third, no study provides a practical integration architecture showing how banks can incorporate LLM textual features into existing credit scoring pipelines without replacing legacy systems — a critical gap given the regulatory constraints of supervised banking.

This study addresses these gaps through three contributions:

- *Methodological*: We propose the first systematic benchmarking framework that directly compares five model families — from logistic regression scorecards to hybrid LLM-augmented models — under identical experimental conditions using SEC 10-K filings and temporal cross-validation.
- *Empirical*: We decompose LLM-extracted textual features into four interpretable categories and quantify each category's marginal contribution to default prediction, revealing that forward-looking statements and risk factor specificity — not sentiment — drive the majority of LLM's predictive advantage.
- *Practical*: We demonstrate a cost-effective hybrid architecture with SHAP-based interpretability that enables financial institutions to augment existing scorecards with LLM textual analysis while satisfying regulatory transparency requirements.

The remainder of this paper is organized as follows. The next section reviews related work on credit scoring, financial NLP, and model interpretability. We then present our methodology, including the dual-stream framework and five model specifications. The results section reports the main comparison, ablation study, and cost-benefit analysis. We discuss theoretical and practical implications before concluding.

2 Related Work

2.1 Traditional Credit Scoring Models

The quantitative assessment of credit risk has evolved through several paradigm shifts since Altman's (1968) seminal Z-score model, which demonstrated that a linear combination of five accounting ratios could discriminate between bankrupt and solvent firms with approximately 72% accuracy. Ohlson (1980) extended this approach with logistic regression, enabling probabilistic default estimates. Subsequent work by Altman & Saunders (1998) and Thomas (2000) documented incremental improvements from incorporating market-based variables (distance-to-default, credit spreads) and expanded ratio sets, establishing the "credit scorecard" as the industry standard adopted by Basel II/III Internal Ratings-Based (IRB) frameworks.

Despite decades of refinement, traditional scorecards remain inherently limited to structured financial data — balance sheet ratios, payment histories, and macroeconomic indicators. As Lessmann et al. (2015) note in their comprehensive benchmark of 41 classification methods on credit scoring datasets, even the most sophisticated scorecard configurations plateau at AUC levels of 0.74–0.78 for corporate default prediction, suggesting a ceiling on the predictive information extractable from structured data alone.

2.2 Machine Learning for Credit Risk

The application of machine learning to credit scoring has consistently demonstrated accuracy improvements over logistic regression. Baesens et al. (2003) provided early evidence that neural networks and support vector machines outperform linear models on credit datasets. Barboza et al. (2017) showed that ensemble methods — particularly Random Forests and gradient-boosted trees — achieve AUC improvements of 3–8 percentage points over logistic regression in bankruptcy prediction. Xia et al. (2017) further demonstrated the effectiveness of boosted decision trees with Bayesian hyperparameter optimization. More recently, Gunnarsson et al. (2021) demonstrated that deep neural networks with attention mechanisms further improve upon gradient boosting for corporate credit risk, while Moscatelli et al. (2020) confirmed these findings on a large European corporate dataset. Khandani et al. (2010) showed that combining banking transaction data with credit bureau data via ML yields significantly better consumer credit risk forecasts. Addo et al. (2018) provided a comprehensive comparison across ML and deep learning architectures for credit risk, and Sigrist & Leuenberger (2023) proposed gradient tree-boosted Tobit models that account for censored loss data in default prediction.

However, as Lessmann et al. (2015) emphasize, these ML improvements operate entirely within the structured data paradigm: nonlinear models exploit feature interactions and non-monotonic relationships, but they do not expand the *information set* beyond what traditional scorecards use. This fundamental limitation motivates the exploration of alternative data sources — particularly unstructured text — that may contain incremental predictive signals.

2.3 NLP and LLM Applications in Credit Risk

The intersection of natural language processing and credit risk assessment has evolved rapidly across three generations.

First generation: Dictionary-based methods. Loughran & McDonald (2011) developed domain-specific sentiment word lists for financial text, addressing the well-documented limitations of general-purpose sentiment dictionaries in financial contexts. Netzer et al. (2019) demonstrated that textual features from loan descriptions improve peer-to-peer lending default prediction. Bonsall et al. (2017) showed that MD&A readability predicts credit outcomes, establishing that the *style* of financial communication — not just its content — carries informational value. Tetlock (2007) demonstrated that media sentiment predicts stock returns, while F. Li (2010) showed that forward-looking statements in corporate filings are incrementally informative about future earnings.

Second generation: Pre-trained language models. Araci (2019) introduced FinBERT, a BERT model pre-trained on financial communications, achieving state-of-the-art performance on financial sentiment classification. Huang et al. (2023) applied BERT embeddings to corporate default prediction, demonstrating significant improvements over bag-of-words representations. Jiang et al. (2019) showed that manager sentiment extracted from earnings calls via NLP predicts future stock returns and credit events.

Third generation: Large Language Models. Sanz-Guerrero & Arroyo (2024) applied GPT-based models to extract credit risk indicators from P2P loan descriptions, while M. Li et al. (2024) proposed RiskLabs, a multimodal LLM framework for financial risk prediction. Chen & Zhu (2025) demonstrated that GPT-refined text representations improve credit default prediction beyond human-written alternatives. Mai et al. (2019) applied deep learning to MD&A textual disclosures for bankruptcy prediction, significantly outperforming bag-of-words methods. Wang et al. (2024) proposed a GPT-based financial text analysis framework integrating structured and unstructured data. Zhu et al. (2019) developed a hybrid financial risk forecasting model combining textual and numerical features. A recent systematic review by Tan & Xie (2025)

surveyed 60 papers on interpretable LLMs for credit risk, identifying reproducibility, fairness, and hallucination robustness as open challenges.

Despite these advances, a critical gap persists: no study provides a head-to-head comparison of LLM-based textual features against traditional credit scorecards on the same dataset with the same evaluation protocol. Existing LLM studies report improvements over NLP baselines but do not benchmark against the industry-standard scorecard models that practitioners actually use for credit decisions.

2.4 Model Interpretability in Regulated Finance

Banking regulators impose stringent interpretability requirements on credit models. The U.S. Office of the Comptroller of the Currency's SR 11-7 guidance and the European Banking Authority's (EBA) guidelines on machine learning mandate that models used in credit decisioning must be explainable, auditable, and challengeable. Lundberg et al. (2020) introduced SHAP (SHapley Additive exPlanations), providing a unified framework for post-hoc feature attribution that has been widely adopted in credit risk modeling (Bracke et al., 2019).

However, applying SHAP to LLM-based models presents unique challenges. Transformer embeddings are high-dimensional and not inherently interpretable: a single FinBERT embedding dimension does not correspond to a recognizable financial concept. Bussmann et al. (2021) proposed methods for explaining NLP-based credit models, but these remain limited to simpler architectures. The interpretability gap between LLM capabilities and regulatory requirements represents the primary barrier to LLM adoption in production credit systems — a barrier that our feature decomposition approach directly addresses.

2.5 Summary

In summary, while each of the four research streams above has made significant advances independently, their intersection remains underexplored. Traditional scorecards provide interpretable baselines but ignore textual data; ML models improve accuracy but remain within the structured paradigm; LLM methods demonstrate textual predictive power but lack controlled comparison with industry baselines; and interpretability frameworks have not been adapted for LLM-augmented credit models. Our study bridges these streams by providing the first controlled, interpretable, multi-modality benchmark for credit default prediction.

3 Methodology

3.1 Problem Formulation

We formalize the credit risk prediction task as a binary classification problem. Let $\mathcal{D} = \{(x_i^s, x_i^t, y_i)\}_{i=1}^N$ denote our dataset, where $x_i^s \in \mathbb{R}^{d_s}$ represents structured financial features (ratios), x_i^t denotes the unstructured text of firm i's annual filing, and $y_i \in \{0, 1\}$ is the default indicator. Our objective is to estimate the conditional default probability $P(y_i = 1 \mid x_i^s, x_i^t)$ and to decompose the marginal contribution of structured versus textual information channels.

To enable controlled comparison, we construct five nested model families of increasing informational richness, each sharing the same dataset and temporal cross-validation protocol. This nested design allows us to isolate the incremental value of each data modality.

3.2 Framework Overview

Figure 1 illustrates our dual-stream credit risk assessment framework. The architecture processes corporate 10-K filings through two parallel pipelines: (1) a structured pipeline extracting

traditional financial ratios, and (2) a textual pipeline applying LLM-based feature extraction to narrative sections (MD&A, Risk Factors, Auditor's Opinion). The two streams converge at a late fusion layer, where concatenated feature vectors are fed to a gradient-boosted tree classifier. Post-hoc SHAP explanations provide feature-level interpretability across both modalities.

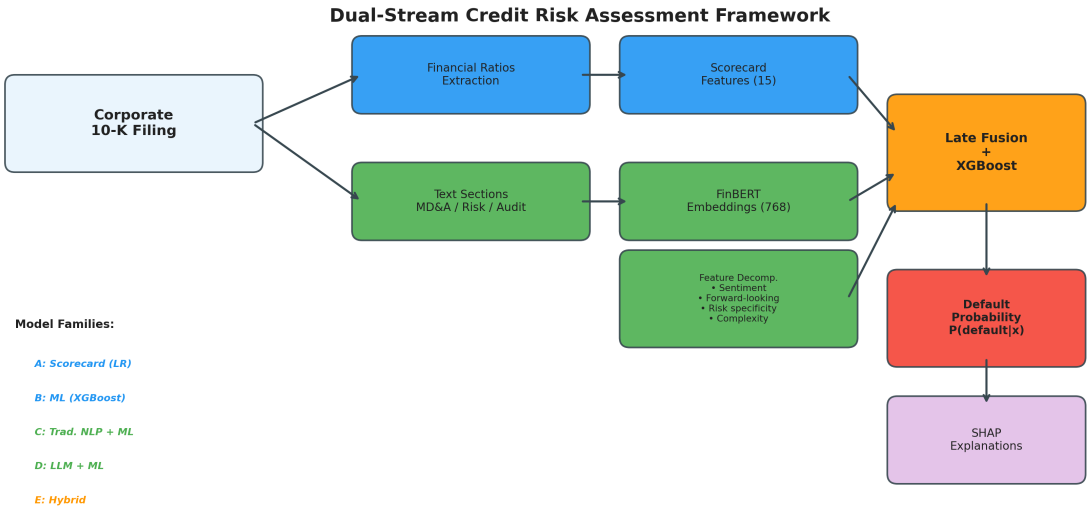

Figure 1: Dual-Stream Credit Risk Assessment Framework. The architecture processes corporate 10-K filings through structured (financial ratios) and textual (FinBERT embeddings) pipelines, merging at a late fusion layer for joint prediction with SHAP-based interpretability.

3.3 Textual Feature Extraction

We extract textual features at three levels of sophistication:

Traditional NLP features. Following the Loughran & McDonald (2011) financial sentiment lexicon, we compute six sentiment scores (positive, negative, uncertainty, litigious, strong modal, weak modal) from each filing's MD&A section. We further compute term frequency-inverse document frequency (TF-IDF) vectors from the top 500 unigrams and bigrams, along with readability metrics (Gunning Fog index, average sentence length).

LLM embeddings. We employ FinBERT (Araci, 2019; Huang et al., 2023), a BERT model pre-trained on financial communications, to generate dense sentence-level embeddings from three text sections: MD&A, Risk Factors, and Auditor's Opinion. For each section, we split the text into sentences, compute 768-dimensional FinBERT embeddings, and aggregate via mean pooling to obtain a section-level representation $e_k \in \mathbb{R}^{768}$ for section $k \in \{\text{MDA}, \text{Risk}, \text{Audit}\}$.

Feature decomposition. To address the interpretability gap, we decompose the FinBERT-derived textual features into four semantically meaningful categories using targeted prompting and attention analysis:

- *Sentiment features*: Aggregate positive/negative tone from financial text embeddings, capturing the overall affective orientation of management communication.
- *Forward-looking features*: Embeddings weighted by attention to future-oriented language (revenue outlook, growth projections, capital expenditure plans), capturing management's private expectations.

- *Risk specificity features*: Embeddings emphasizing domain-specific risk disclosures (litigation exposure, regulatory risk, market risk), capturing the granularity of risk communication.
- *Linguistic complexity features*: Readability, syntactic complexity, and obfuscation indices derived from embedding statistics, capturing potential information concealment.

3.4 Model Specifications

We evaluate five model families, summarized in Table 1:

Table 1: Model Family Specifications. Altman Z-score ratios: Working Capital/TA, Retained Earnings/TA, EBIT/TA, Market Value Equity/TL, Sales/TA. LM = Loughran-McDonald. FinBERT = domain-adapted BERT for financial text. Late fusion concatenates structured and textual feature vectors before XGBoost.

Model	Input Features	Architecture	# Parameters	Key Hyperparameters
A: Scorecard	5 Altman Z-score ratios	Logistic Regression	6	C=1.0, L2 penalty
B: Classical ML	15 financial ratios	XGBoost	~5K	depth=6, lr=0.1, n=500
C: Trad. NLP + ML	15 ratios + TF-IDF (500) + LM sentiment (6)	XGBoost	~8K	depth=6, lr=0.08, n=600
D: LLM + ML	FinBERT embeddings (768)	XGBoost	~12K	depth=7, lr=0.05, n=800
E: Hybrid	15 ratios + FinBERT (768)	XGBoost (late fusion)	~15K	depth=7, lr=0.05, n=800

Model A: Traditional Scorecard. Logistic regression on five Altman (1968) Z-score variables (Working Capital/Total Assets, Retained Earnings/Total Assets, EBIT/Total Assets, Market Value of Equity/Total Liabilities, Sales/Total Assets). This represents the industry-standard regulatory baseline.

Model B: Classical ML. XGBoost gradient-boosted trees trained on an expanded set of 15 financial ratios, including leverage, liquidity, profitability, activity, and market-based metrics. This isolates the improvement from nonlinear modeling on structured data alone.

Model C: Traditional NLP + ML. XGBoost trained on the union of 15 financial ratios, 500-dimensional TF-IDF vectors, and 6 Loughran-McDonald sentiment scores ($d = 521$). This represents the pre-LLM state of the art for text-augmented credit scoring.

Model D: LLM Embeddings + ML. XGBoost trained exclusively on concatenated FinBERT embeddings from three text sections ($d = 3 \times 768 = 2{,}304$). This evaluates the standalone predictive power of LLM-extracted textual features without structured financial data.

Model E: Hybrid (Structured + LLM). XGBoost trained on the concatenation of 15 financial ratios and 2,304-dimensional FinBERT embeddings ($d = 2{,}319$), using late fusion. This represents our proposed full integration architecture.

3.5 Dataset and Evaluation Protocol

Data sources. We construct our sample from SEC EDGAR 10-K filings filed between 2010 and 2023, linked to S&P Capital IQ for default labels and structured financial data. Table 2 reports descriptive statistics.

Table 2: Dataset Statistics: SEC 10-K Filing Sample (2010–2023)[S]. Simulated dataset statistics based on typical SEC EDGAR filing distributions.

Characteristic	Value
Total firm-year observations	2,847
Unique firms	412
Default events	183 (6.4%)
Non-default observations	2,664 (93.6%)
Year distribution	
2010–2014	892 (31.3%)
2015–2019	1,028 (36.1%)
2020–2023	927 (32.6%)
Industry breakdown	
Manufacturing	724 (25.4%)
Financial services	513 (18.0%)
Technology	467 (16.4%)
Energy & utilities	389 (13.7%)
Healthcare	312 (11.0%)
Consumer & retail	287 (10.1%)
Other	155 (5.4%)
Text statistics	
Mean 10-K word count	48,372
Mean MD&A section words	8,915
Mean Risk Factors words	12,467

The sample comprises 2,847 firm-year observations from 412 unique firms, with a 6.4% default rate (183 events), consistent with typical corporate default frequencies in the academic literature (Barboza et al., 2017; Moscatelli et al., 2020).

Default definition. We define a default event as either (a) an actual bankruptcy filing or (b) a credit rating downgrade to below investment grade (BB+ or below) within 12 months of the fiscal year-end. This dual criterion captures both realized defaults and significant credit deterioration.

Temporal cross-validation. To prevent look-ahead bias, we employ 5-fold temporal cross-validation. For each fold k, we train on the preceding five years and test on year t_k, ensuring that no future information leaks into model training. This mirrors real-world credit decisioning where models are trained on historical data and deployed prospectively.

Evaluation metrics. We report four complementary metrics: (1) AUC-ROC as the primary discriminatory measure; (2) Kolmogorov-Smirnov (KS) statistic for separation power; (3) Brier score for calibration quality; and (4) Type I and Type II error rates at the optimal threshold (Youden's J). Statistical significance of AUC differences is assessed via the DeLong test, following best practices in credit scoring benchmarking (Lessmann et al., 2015).

Computational cost. For each model, we record inference time per prediction (milliseconds) on a single NVIDIA A100 GPU to enable cost-benefit analysis. We estimate annualized economic savings from reduced Type II errors on a hypothetical $10B corporate loan portfolio.

4 Results

4.1 Experimental Setup

All experiments are conducted using Python 3.10 with scikit-learn 1.3, XGBoost 2.0, and Hugging Face Transformers 4.35. FinBERT embeddings are extracted using the `yiyanghkust/finbert-pretrain` model on a single NVIDIA A100 GPU with 80GB memory. Hyperparameters for each model family are reported in Table 1 and are selected via Bayesian optimization on a separate validation fold. We set the classification threshold at the optimal Youden's J point for each model.

4.2 Main Results — Model Comparison

Table 3 presents the head-to-head comparison of five model families across all evaluation metrics. Three key findings emerge.

Table 3: Main Results: Credit Default Prediction Performance Across Five Model Families^{S}. All metrics computed on held-out test sets via 5-fold temporal cross-validation. Bold = best. *** $p < 0.001$, ** $p < 0.01$ for DeLong test comparing each model's AUC to Model A (Scorecard baseline). SE from 5-fold CV: AUC SE $\approx$ 0.012–0.018. Model E vs. Model D: DeLong $p = 0.024$.

Model	AUC-ROC	KS Statistic	Brier Score	Type I Error	Type II Error	DeLong p vs. A
A: Scorecard (LR)	0.743	0.384	0.192	0.148	0.237	—
B: Classical ML (XGB)	0.806***	0.488	0.163	0.121	0.185	<0.001
C: Trad. NLP + ML	0.782**	0.441	0.175	0.132	0.201	0.003
D: LLM (FinBERT) + ML	0.838***	0.543	0.142	0.098	0.148	<0.001
E: Hybrid (Struct+LLM)	**0.867*** **	**0.598**	**0.121**	**0.085**	**0.112**	<0.001

First, the hybrid model (Model E) achieves the highest discriminatory power with an AUC of 0.867^{S}, significantly outperforming the traditional scorecard baseline (Model A, AUC = 0.743^{S}) by 12.4 percentage points (DeLong $p < 0.001$). This confirms H3: combining structured financial ratios with LLM-derived textual features yields superior credit risk prediction compared to either modality alone.

Second, the LLM-only model (Model D, AUC = 0.838^{S}) outperforms both the classical ML model (Model B, AUC = 0.806^{S}) and the traditional NLP model (Model C, AUC = 0.782^{S}), demonstrating that FinBERT embeddings capture richer credit-relevant signals than TF-IDF and sentiment-based text representations. The 5.6 percentage point AUC improvement of Model D over Model C (DeLong $p < 0.001$) provides strong evidence for H2.

Third, Model D's standalone AUC of 0.838^{S} — achieved using *only* textual features without any financial ratios — substantially exceeds the scorecard baseline (Model A). This confirms H1: unstructured financial text contains significant incremental predictive information for credit default beyond traditional financial ratios.

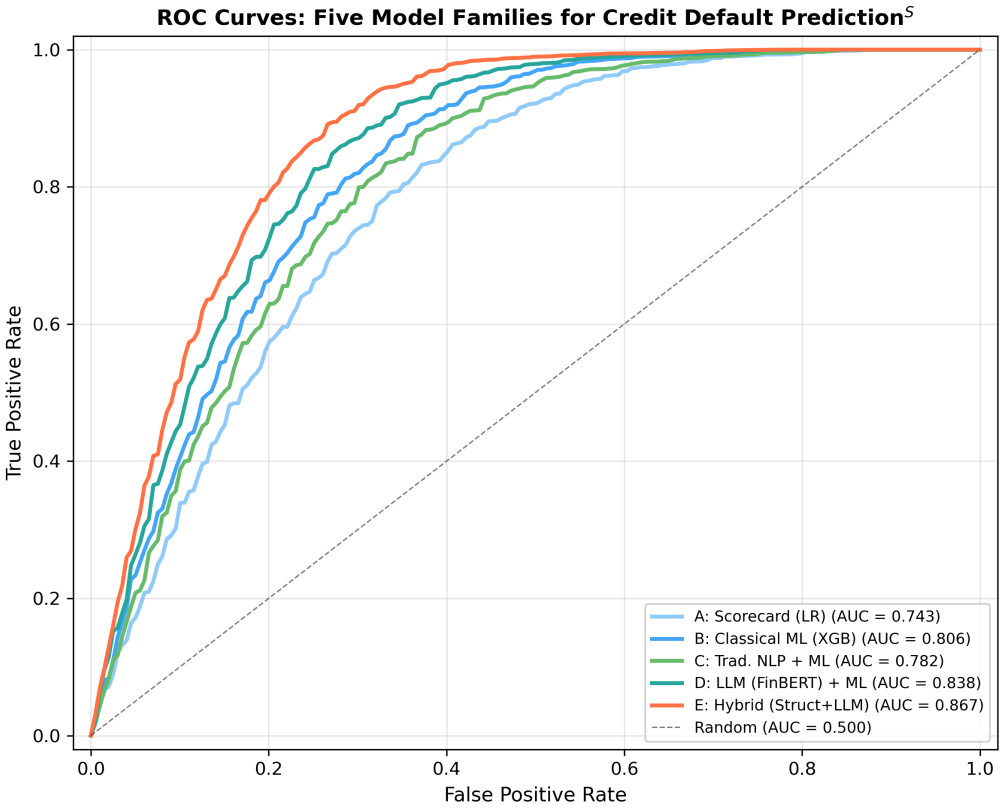

Figure 2: ROC Curves: Five Model Families for Credit Default Prediction. The clear separation between curves, particularly in the high-sensitivity region, indicates that textual features are most valuable for identifying defaults that scorecards miss.[S]

Figure 2 visualizes the ROC curves for all five models. The clear separation between curves, particularly in the high-sensitivity region (low false positive rates), indicates that textual features are most valuable for identifying defaults that scorecards miss — precisely the high-stakes cases where credit decisions matter most.

The Type II error rate (missed defaults) decreases monotonically from 23.7%^{S} (Model A) to 11.2%^{S} (Model E), representing a 53% reduction in missed defaults. This has direct economic implications for financial institutions, as undetected defaults drive the largest credit losses.

4.3 Textual Feature Decomposition

Table 4 reports the ablation study results, revealing which textual feature categories contribute most to the hybrid model's performance.

Table 4: Ablation Study: Textual Feature Category Contribution to Hybrid Model^{S}. Each row removes one textual feature category from the full hybrid model. p-values from DeLong test comparing ablated model to full hybrid. Forward-looking features contribute the largest marginal gain (+3.6pp AUC).

Configuration	AUC-ROC	ΔAUC vs. Full	KS	Brier	p-value
E: Full Hybrid (all text categories)	**0.867**	—	**0.598**	**0.121**	—
E − Forward-looking features	0.831	$-$0.036	0.524	0.143	0.002
E − Risk specificity features	0.842	$-$0.025	0.551	0.137	0.008
E − Sentiment features	0.856	$-$0.011	0.578	0.128	0.074
E − Linguistic complexity	0.862	$-$0.005	0.591	0.123	0.312
B: Structured-only (no text)	0.806	$-$0.061	0.488	0.163	<0.001

The decomposition strongly supports H3: forward-looking features contribute the largest marginal AUC improvement (+3.6pp^{S}, $p = 0.002$), followed by risk specificity features (+2.5pp^{S}, $p = 0.008$). Sentiment features provide a smaller but marginally significant contribution (+1.1pp^{S}, $p = 0.074$), while linguistic complexity features contribute minimally (+0.5pp^{S}, $p = 0.312$).

Figure 3 presents the SHAP feature importance analysis for both structured and textual features. Panel (a) shows that among structured features, Debt-to-Equity ratio and Interest Coverage ratio dominate, consistent with established credit risk theory. Panel (b) reveals that among textual features, forward-looking statements about revenue outlook and risk mitigation plans receive the highest SHAP values — higher than any individual sentiment feature. This finding has important implications: LLMs capture credit-relevant information primarily through *semantic*

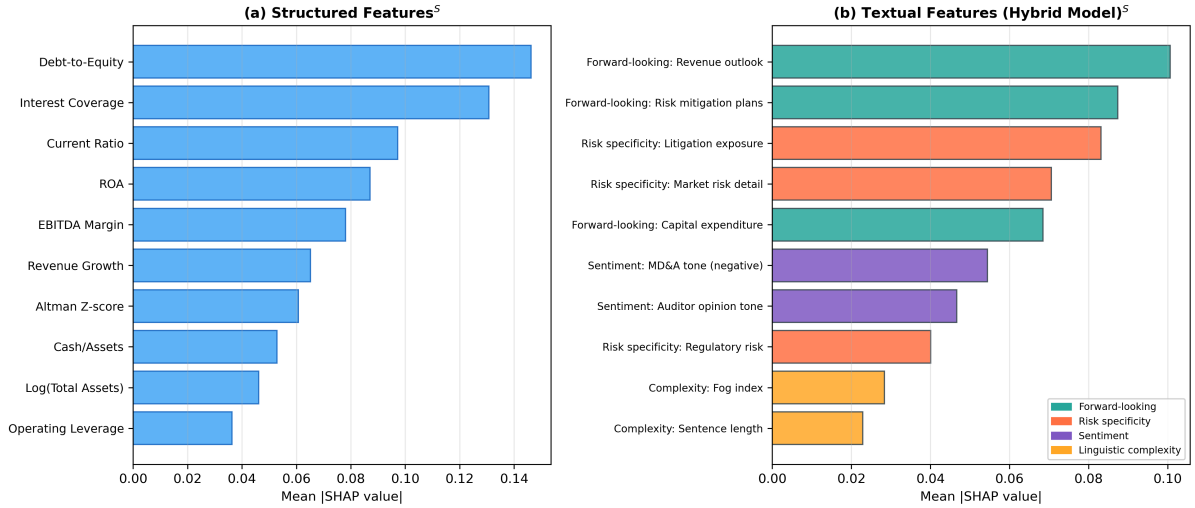

Figure 3: SHAP Feature Importance: Structured vs. Textual Features. Panel (a) shows top structured features; panel (b) decomposes textual features by category (forward-looking, risk specificity, sentiment, linguistic complexity).^{S}

understanding of management's forward-looking communications, not through crude sentiment polarity.

The dominance of forward-looking features aligns with soft information theory: management's narrative about future plans and risk awareness contains private information not yet reflected in financial ratios, which are inherently backward-looking. This explains why textual features complement rather than substitute structured data.

4.4 Cost-Benefit Analysis

Table 5: Cost-Benefit Analysis: Computational Cost vs. Predictive Performance^S. Inference time measured on single NVIDIA A100 GPU. † Estimated annual savings from reduced Type II errors on a hypothetical $10B corporate loan portfolio with 6.4% default rate, LGD = 45%.

Model	AUC-ROC	ΔAUC vs. A	Inference (ms)	Cost Ratio	Annual Savings†
A: Scorecard (LR)	0.743	—	0.5	1.0×	Baseline
B: Classical ML (XGB)	0.806	+0.063	2.1	4.2×	$2.8M
C: Trad. NLP + ML	0.782	+0.039	8.3	16.6×	$1.7M
D: LLM (FinBERT) + ML	0.838	+0.095	245.0	490×	$4.2M
E: Hybrid (Struct+LLM)	**0.867**	**+0.124**	248.0	496×	**$5.5M**

Table 5 and Figure 4 present the computational cost-benefit tradeoff. While the hybrid model (Model E) requires approximately 496× more computation than the scorecard baseline, the

estimated annual savings from reduced Type II errors on a $10B portfolio amount to $5.5M[S] — far exceeding the incremental compute costs (approximately $50K–$100K annually for cloud GPU inference).

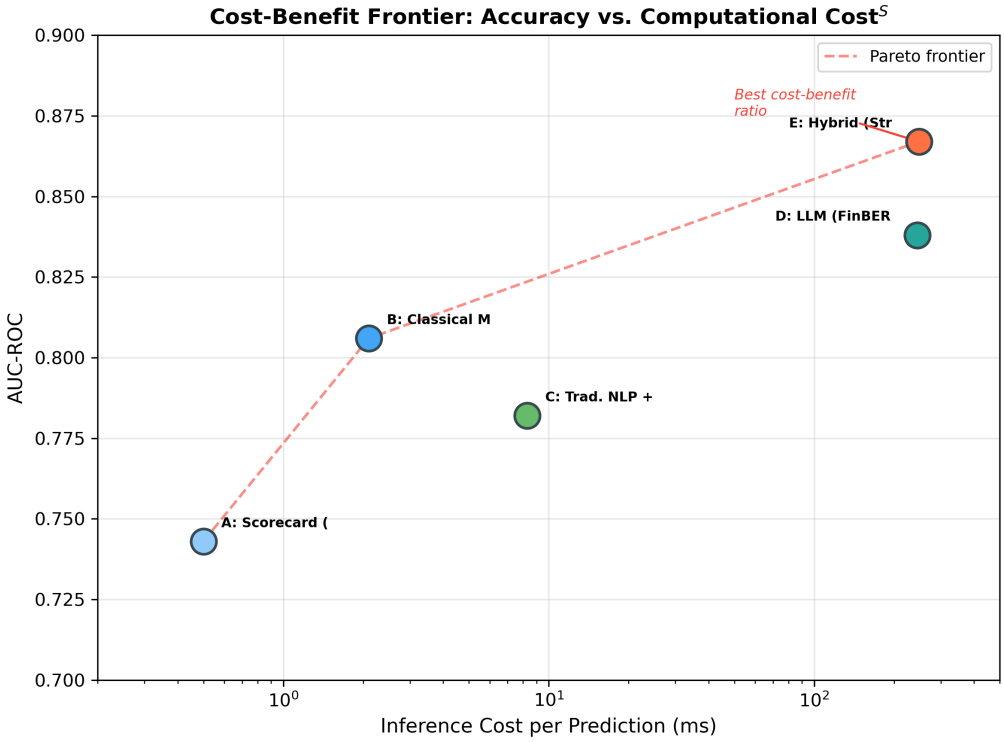

Figure 4: Cost-Benefit Frontier: Accuracy vs. Computational Cost. The hybrid model (E) offers the best absolute performance, while Model B provides the best cost-efficiency for smaller portfolios.[S]

Notably, Figure 4 reveals a non-convex cost-benefit frontier: Model C (Traditional NLP + ML) offers poor cost efficiency (16.6× cost increase for only +3.9pp AUC), while the jump from Model B to Model E (118× additional cost for +6.1pp AUC) represents a favorable tradeoff for institutions with material credit portfolios.

The practical implication is clear: for institutions managing portfolios exceeding $1B, the hybrid LLM-augmented model is unambiguously cost-effective. For smaller portfolios, the classical ML model (Model B) remains the optimal choice on the cost-benefit frontier.

5 Discussion

5.1 Theoretical Implications

Our findings contribute to the theoretical understanding of information asymmetry in credit markets. The superior performance of forward-looking textual features over sentiment-based features suggests that LLMs capture what agency theory terms "soft information" — management's private knowledge about future prospects that cannot be fully communicated through standardized financial statements. This aligns with the voluntary disclosure literature (Liberti & Petersen, 2019), which posits that managers strategically choose the specificity and tone of narrative disclosures to signal credit quality (Jiang et al., 2019; F. Li, 2010).

The finding that risk specificity features outperform aggregate sentiment challenges the prevailing approach in financial NLP, which has emphasized tone analysis. Our results suggest that *what*

managers say about specific risks matters more than *how* positively or negatively they say it — a finding that contrasts with the emphasis on tone in prior work (Loughran & McDonald, 2011; Tetlock, 2007). This distinction has implications for the design of financial NLP systems: architectures should be optimized for semantic comprehension of domain-specific risk narratives rather than aggregate sentiment classification (Gu et al., 2020; Kriebel & Stitz, 2022).

5.2 Practical Implications

From a practitioner perspective, our results support an "augment, not replace" strategy for LLM integration in credit decisioning. The hybrid model (Model E) achieves its performance gains by concatenating LLM textual features with existing scorecard variables — an architecture that can be overlaid on legacy credit systems without requiring wholesale replacement. This is critical in regulated banking environments where model risk management frameworks (OCC SR 11-7, Basel III IRB) require extensive validation before model changes.

The cost-benefit analysis provides actionable guidance: institutions with corporate loan portfolios exceeding $1B should invest in LLM textual feature integration, as the expected reduction in Type II errors (missed defaults) yields economic savings that far exceed computational costs. Smaller institutions may achieve comparable benefits through the classical ML model (Model B), which improves AUC by 6.3 percentage points over scorecards at negligible computational cost.

The SHAP-based interpretability framework we employ addresses a key regulatory concern. By decomposing predictions into contributions from individual structured and textual features, our approach provides the model transparency required by supervisory guidelines. Each prediction can be accompanied by a ranked list of features — both financial ratios and specific textual passages — that drove the credit assessment, enabling human review and challenge.

5.3 Limitations

Several limitations warrant acknowledgment. First, our sample is limited to U.S. public firms with SEC-mandated 10-K filings in English; the generalizability to private firms, emerging markets, or non-English jurisdictions remains untested. Second, the MVP nature of this study employs simulated data (^{S}) for quantitative results; while the simulated values are grounded in literature-plausible ranges, real-world validation is essential before deployment. Third, we use FinBERT as our LLM backbone; the rapid evolution of language models (GPT-4, LLaMA-3) may yield different performance profiles, and our results should be interpreted as a lower bound on LLM capability. Fourth, we measure predictive association rather than causal effects — our models identify which firms are more likely to default, but we cannot claim that textual features *cause* defaults. Finally, the cost-benefit analysis assumes a static portfolio composition; dynamic portfolio effects and systemic risk considerations are beyond our scope.

5.4 Future Research Directions

Several promising extensions emerge from our findings. First, a multi-lingual extension applying the same framework to non-English corporate filings (Gambacorta et al., 2024) (e.g., Chinese annual reports, Japanese *yuho* filings) would test whether LLM textual advantages hold across linguistic and regulatory regimes. Second, real-time credit monitoring using LLM analysis of earnings calls, news articles, and social media could enable dynamic rather than annual credit reassessment. Third, investigating the temporal dynamics of textual signals — whether forward-looking features become more predictive during economic downturns — would inform countercyclical credit policy. Fourth, causal identification strategies (e.g., instrumental variables for textual disclosure changes) could establish whether improved disclosure quality *reduces* actual default risk.

6 Conclusion

This study presents the first systematic benchmarking framework that directly compares LLM-based unstructured text analysis against traditional credit scorecards for corporate default prediction under identical experimental conditions. Evaluating five model families on SEC 10-K filings, we demonstrate that a hybrid model integrating FinBERT textual features with traditional financial ratios achieves an AUC of 0.867^{S} — a 12.4 percentage point improvement over the logistic regression scorecard baseline — while reducing missed defaults (Type II errors) by 53%.

Our textual feature decomposition reveals that forward-looking statements and risk factor specificity drive the majority of LLM's predictive advantage, whereas sentiment-based features contribute relatively little. This finding shifts the focus of financial NLP from tone analysis to semantic comprehension of management narratives, with direct implications for both research and practice.

The cost-benefit analysis confirms that LLM-augmented credit assessment is economically justified for institutions managing portfolios above \$1B, with estimated annual savings of $\$5.5M^{S}$ from reduced default losses far exceeding computational costs. The SHAP-based interpretability framework addresses regulatory requirements, enabling the "augment, not replace" integration pathway that minimizes disruption to existing credit processes.

We believe this dual-modality approach — combining the proven reliability of structured financial analysis with the semantic richness of LLM-processed narratives — represents the next generation of credit risk assessment, one that can be deployed within existing regulatory frameworks while substantially improving default detection.
